Broad relevance of collective behavior

- Observed in wide range of organisms and ecological contexts
 - From bacterial (or cellular) swarms to wildebeests
- Nonequilibrium statistical mechanics of self-driven particles
- Robotics: Coordination of mobile autonomous agents
- Natural Algorithms
- Traffic Organization, Human Crowds, etc.

Question: Individuals to collectives

1. How do individual level interactions scale to collective patterns

Self-ordered collective motion

Video Courtesy: Yael Katz @ CouzinLab

Why such interactions occur?

1. How individual level interactions scale to collective patterns

Individual level interactions

Self-ordered collective motion

- Local interactions can change
 - Over relatively long evolutionary timescales (due to reproduction, mutation and natural selection)

2. Why do such interactions among individuals occur/exist in the natural world?

Individual versus collective benefits

- One may argue that local social interactions lead to emergent group benefits (or mutual benefits to individual members).
 - *e.g.,* Improved navigational and/or foraging ability
- But natural selection does not optimize group properties.
 - It favors individuals with higher relative-fitness, typically leading to conflict among individuals.
- What happens in a migratory context?

Collective motion in migratory species

- Ubiquitous phenomena: Cells to Wildebeests.
 - Involves climbing gradients (magnetic, resource, etc).
- Massive number of individuals

Collective migration: hints on mechanism

A self-propelled particle model for collective migration

- We will consider following two individual traits
 - Ability to sense environmental gradient/cues
 - Geomagnetic field, resource, thermal, chemical and/or electromagnetic fields.
 - Ability to socially interact with neighbors
 - Respond to neighbors motion, *e.g.*, through visual or chemical cues.
- Given a need to migrate in a specific direction:
 - How do individuals optimize above two traits.
- Individuals (self-propelled particles) move
 - in a continuous two-dimensional space
 - with constant speed
 - update their direction of motion in discrete time steps.

Solitary migration

• Environment: a global migratory gradient along x-axis.

Migratory direction

- Trait 1: Gradient detection trait (ability): ω_{gi}
 - Determines how accurately an individuals find migratory direction.

$$\dot{\theta}_i = -\omega_{gi}\theta_i(t) + \sigma_g\eta_{gi}(t)$$

For simplicity, assume temporally uncorrelated noise.

V Guttal and I D Couzin, 2010, PNAS, Vol: 107: 16172-16177 Based on Couzin et al, Nature, 2005

Migratory benefits

• b_i = distance moved in the direction of gradient, per unit time

V Guttal and I D Couzin, 2010, PNAS, Vol: 107: 16172-16177

Costs of gradient detection ability

$$c_{gi} = p_g(e^{\omega_{gi}/\omega_{gc}} - 1.0)$$

- p_q has same units as migratory benefits.
- Different magnitude of costs is obtained by varying p_a

V Guttal and I D Couzin, 2010, PNAS, Vol: 107: 16172-16177

Individual migratory fitness

• Fitness (reproductive success) = Benefit – Cost.

- Solitary individual optimum.
- What if we allow flocking interactions between individuals?

Collective motion

• Trait 2: Flocking/ Social interactions: ω_s

Denote position by $\mathbf{c}_i(t)$ and velocity by $\mathbf{v}_i(t)$

Repulsion: Avoid others within a body length r_a

Sociality: a tendency to attract towards, and align direction of travel, with neighbors within radius r_s (outer radius)

$$\mathbf{d}_{\mathbf{si}}(t + \Delta t) = \sum_{j \neq i} \frac{\mathbf{c}_j(t) - \mathbf{c}_i(t)}{|\mathbf{c}_j(t) - \mathbf{c}_i(t)|} + \sum_{j=1} \frac{\mathbf{v}_j(t)}{|\mathbf{v}_j(t)|}$$

Based on Couzin et al, Nature, 2005

Plausible population level dynamics

Individual traits are determined by natural selection

- We do not predetermine what the individual traits in the population are.
- It is going to be determined by natural selection.
 - Individuals may possess only gradient detection ability.
 - Or only social interactions and thus, follow nearby individuals.
 - Or a combination of both.
 - Evolved populations may also be heterogeneous.

Plausible population level dynamics

• Where would evolved populations be in this parameter space?

Selection algorithm

- Start with a large homogeneous population (large sizes: 16,000 to 60,000 individuals)
- They move according to the equations of motion over one generation (averaged over several realizations).

Calculate Fitness:

- Find benefit for each individual
- Find cost of gradient detection depending on its ω_g
- Calculate Fitness = Benefit Cost.

• Reproduce proportional to fitness (Roulette Wheel Selection)

- Asexual reproduction
- The gradient detection ability, ω_g and the sociality trait, ω_s of the parent are passed on to offspring with a small mutation.
- Repeat the process until an equilibrium of trait/phenotype distributions is reached.

Evolved strategies:

• No cost of gradient climbing:

Gradient detection ability

Evolved strategies:

• Very high cost of gradient climbing:

Gradient detection ability

Evolved strategies:

• Intermediate cost of gradient climbing:

Gradient detection ability

Solitary versus social strategies

With Yu Zou, Couzin and Kevrekidis

Phase diagram of evolved populations

Very low density and/or low cost.

=> Individual migratory strategies

Large intermediate region Collective migratory strategies

Role of social interactions

- It allows *exploitation* of leaders *i.e.*, those who invest in sensing environment are exploited by *social individuals* who only follow others naively.
- They both coexist as a mixed strategy, resulting in collective migration.
- In our model, evolved collective migratory populations migrate less efficiently than solitary populations.
